3 Sizing Methodology for Integrated SMA Actuators

3.1 Introduction

In the past few decades, there has been a growing need for miniaturisation. Modern devices have come to require actuators that are compact and lightweight. As mentioned previously, since SMAs have been known to show the highest volumetric work density, they have been increasingly used in applications where compactness and low weight are required.

As previously presented in chapter 1, SMA actuators require an active element, a biasing element and a kinematic stage for motion control. These components, usually discrete elements, when combined together create an SMA actuator that can preform a specific reversible work, such as gripping or crawling motionscite. With the objective of miniaturisation, most work has been conducted into rendering these individual components as compact and lightweight as possiblecite. But the fact that these stages are discrete, lowers the overall volumetric work density of the complete actuator. Furthermore, as multiple systems are needed, the actuator also requires various pieces and assembly increasing the complexity and decreasing the compactness.

Recently, there has been a shift in creating novel motion control mechanisms using flexure-based mechanisms. These flexures are multiple compliant elements designed so as to only be compliant in specific degrees of freedom while being rigid in the others. These mechanisms, which can be fabricated using a monolithic piece of material, are lightweight and require virtually no assembly. These flexural stages, when paired with SMAs, have greatly increased the overall work density of the traditional SMA actuatorscite.

These flexure-based mechanisms are still often integrated into the SMA actuators as discrete mechanisms. In this chapter, the concept of integrating the biasing element as a flexural mechanism is explored. In this case, the kinematic stage and the biasing element are combined and are no longer discrete systems within the mechanism. Some research has been shown to take into account flexure mechanisms in SMA actuators but they lack a suitable sizing strategy due to the complexity of the shape memory effect and the nonlinear nature of flexurescite.

Thus, in this chapter, this novel design methodology is presented and analysed using an analytical model.

3.2 Adapted Design Concept

As mentioned previously, most SMA actuators are composed of an active element, a biasing element and a kinematic stage charged with converting the linear output of the actuator into a more complex one. In general, these elements are discrete components ranging from SMA coils, passive biasing springs and the kinematic stage comprised of hinges and linear slides. As presented in fig. 3.1, the design methodology consists of integrating the kinematic stage and the biasing element.

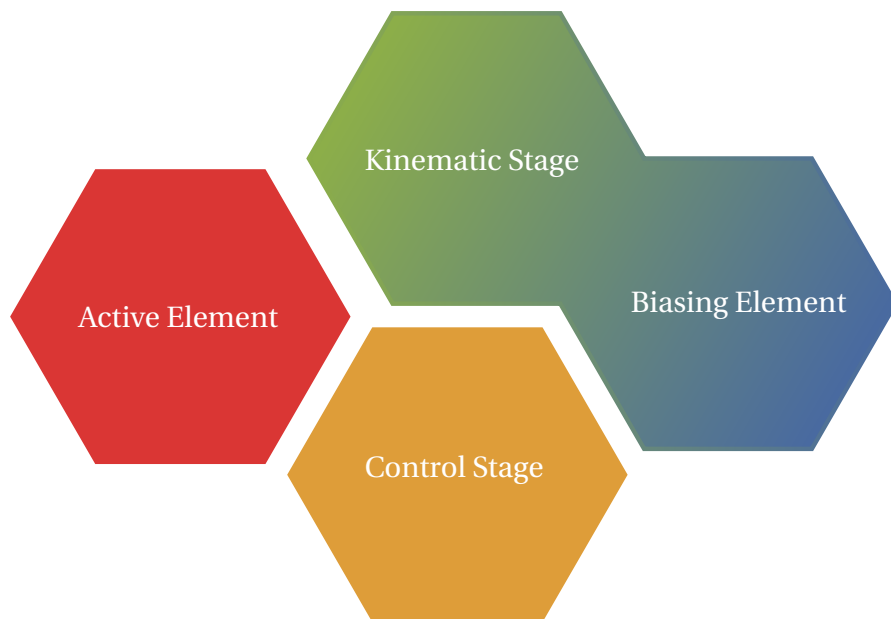

Figure 3.1: Diagram of the adapted building blocks of the SMA actuator.

This integration can be accomplished with the use of flexure-based mechanisms. Generally, flexures have been used in creating an alternative solution for traditional hinges and linear slides. These flexures are comprised of cantilever beams which allows the mechanism to be compliant in a specific degree of freedom while being rigid in the others. The advantages of such a system is that when adequately design can result in a kinematic stage that is lightweight, lacks any assembly and has high precision.

The main drawback to such a system compared to traditional bearings is the inherent stiffness of the mechanism. As these flexures are composed of compliant beams, the rigidity of the beam must be taken into account. In the case of an SMA actuator, this rigidity of the compliant structure can be harnessed as the biasing element. This implies that by pairing the active SMA element with a flexure, the kinematic stage and the biasing element can be combined. This novel approach can be used to create biased SMA actuators that are precise, lightweight and

with a limited number of pieces to be assembled.

3.3 Challenges of the Approach

Due to the complex nature of the shape memory effect, the principle challenge when it comes to designing such SMA actuators is the difficulty in sizing the active SMA based on the flexure mechanism. Based on the configuration of the flexural stage, this mechanism can present highly nonlinear behaviour as well. When paired with an SMA wire or coil, this can result in unintended behaviours or secondary operating points.

Recently there has been research such as the work by Maffiodo et al. (2017) that shows the advantages of pairing SMA wires with flexure-based structures. As with this case, the sizing of the SMA element is disregarding and the biasing advantage of the flexure is neglected.

In the case of grippers and mesoscale actuators where the SMA element is passively cooled, the accurate sizing of the SMA is important. In designs, where passive cooling is used, the geometry of the active element is critical as the shape and structure of the active element is directly related to the cooling times. In the case of SMA coils and wires, thinner diameters imply a shorter cooling time. These thinner wires, however, result in smaller forces when heated. This implies that by accurately sizing the SMA element for the biasing flexure, the actuator can be made as thin as possible while still being able to deform the flexure during heating. Thus, by adapting the traditional sizing methodology of bias-spring SMA actuators for flexure-based designs, the SMA actuator can be designed with faster response times.

3.4 Adapting the Simplified Models

In section 2.5, a simplified model of the SMAs are used to size the active element for bias-spring and antagonistic SMA actuators. In the traditional sizing strategy, a simplified linear model of the SMA and the curve of the spring are used to find the operating points of the actuator which is represented by the intersection of the two curves. This simplification allows a relatively simpler sizing of the components by abstracting the complex nonlinear behaviours of the shape memory effect.

3.4.1 Passive Biasing Compliant Mechanisms

The compliant mechanism, as mentioned previously, acts as the biasing element and as the kinematic stage that produces the desired actuator motion. Here, the basic principle is that the inherent stiffness of the compliant flexure mechanism is harnessed to pre-load the SMA for activation. In this case, at lower temperatures, the SMA is deformed using the energy stored in the compliant mechanism while at higher temperatures, the strain recovered by the shape memory effect is used to deform the compliant mechanism. Based on the design of the

compliant mechanism, the SMA actuator can be made to actuate reversibly in a single degree of freedom while being rigid in the others.

In order to size the actuator and its corresponding passive biasing compliant element, an analytical model can be devised and exploited to predict the various operating points of the final SMA actuator. A pseudo-rigid body model (PSBM) based on the work by [cite](#) can be used to devise the analytical models of the flexures. The flexure hinges are considered to behave like torsional springs with constant angular stiffness, K_θ . The analytical model can be derived by considering the reaction force exerted by the mechanism on the SMA wire or coil when acting as the biasing element.

While a Newtonian approach is possible, the simplest way to compute the force is to consider the elastic potential energy stored in the flexure hinges as the mechanism deforms. This potential energy stored in one torsional spring as a function of the input displacement of the mechanism, Δx , as given by :

$$U(\Delta x) = \frac{1}{2} K_\theta (\theta(\Delta x) - \theta_0)^2 \quad (3.1)$$

where, in the case of a notch flexure hinge, as shown in fig. 3.2, when rotating by an angle of θ , has a stiffness, as described in [cite](#), equal to:

$$K_\theta = \frac{2Ebe^{2.5}}{9\pi\sqrt{r}} \quad (3.2)$$

Here, E is the Young modulus of the material, and e, b and r the design parameters of the flexure hinge shown in fig. 3.2.

Figure 3.2: A diagram of the notch flexure hinge.

In this approach, the important relationship to obtain is the influence of the contraction of the SMA on the rotation of the hinge, $\theta(\Delta x)$. When the flexure-based system is comprised of multiple flexural hinges, the total potential energy can be calculated by the sum of the potential elastic energy of each flexure, $U_{\text{tot}} = \sum U(\Delta x)$. The required force to deform the

structure can be deduced using :

$$F(\theta(\Delta x)) = \|\nabla U_{\text{tot}}(\Delta x)\| = \frac{\partial U_{\text{tot}}(\Delta x)}{\partial \Delta x} \quad (3.3)$$

Figure 3.3: The adapted sizing principle of the novel biasing compliant mechanism SMA actuator based on the simplified SMA curves.

As in the case of the traditional SMA sizing methodology, the intersection between the adapted biasing curve and the simplified SMA curves represents the operating points of the SMA actuator, visualised in fig. 3.3 as ① and ②. The stroke of the actuator can be estimated by taking the different between the x-coordinate of the operating points, $x_1 - x_2$. It is important to note that there is a maximum pull force that the SMA wire or coil can exert, as seen in [cite](#). Thus, the SMA element must be sized such that $F_1 < F_{\text{max}}$ so as to obtain the thinnest SMA wire or coil which can still exert enough force to deform the compliant mechanism to the required stroke.

In fig. 3.4, the design methodology for sizing a biased-compliant mechanism SMA actuator is presented. The methodology consists of designing the SMA active element based on the desired time response (τ) specifications of the application. As explained previously, in the case of passive cooling applications, the wire diameter can be reduced to decrease cooling times and increase τ . Once the diameter of the SMA wire or coil is determined, the biasing element can be designed. In the case of a biasing compliant mechanism, the flexure hinges can be designed based on the desired stroke of the application. As fig. 3.4 details, the operating points must be estimated using the design of the compliant mechanism. The structure and design of the compliant mechanism can be used to determine the relationship between the strain recovered by the SME and rotation of the flexural hinges, $\theta(\Delta x)$. This relationship can be used to determine the force-displacement curve of the resulting biasing element using the

equation presented in eq. (3.1). Finally, the individual flexural hinges can be adjusted such that the desired stroke, Δx , is obtained and that the maximum pull force of the SMA wire or coil is not exceeded.

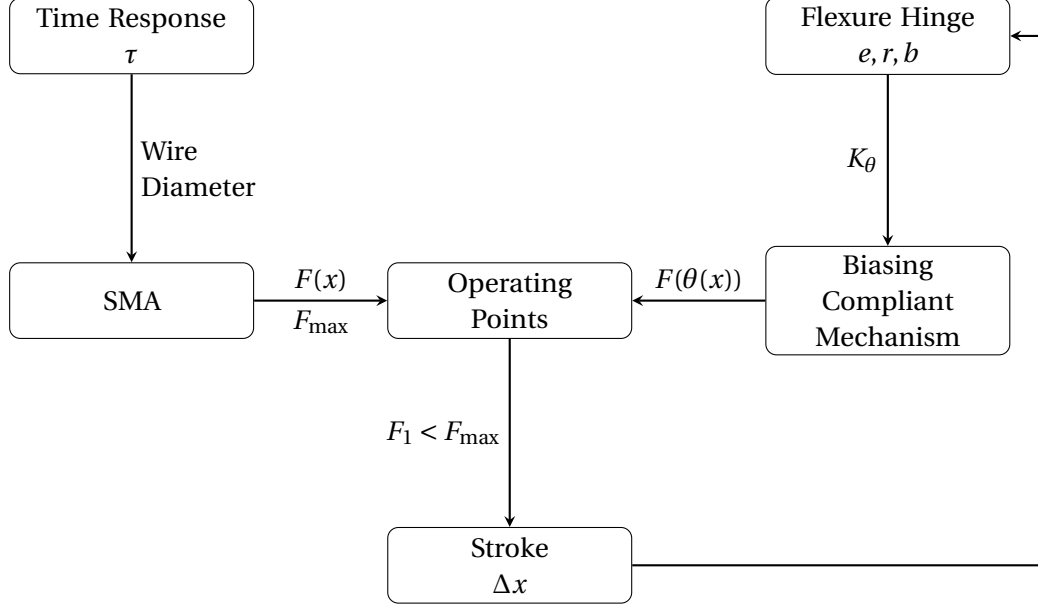

Figure 3.4: Design methodology for sizing biased-compliant mechanism SMA actuators.

3.4.2 Integration of Compliant Mechanisms in Antagonistic SMA Actuators

The concept of augmenting traditional bias-spring SMA actuators with compliant mechanisms can be extended to Antagonistic SMA actuators. Traditionally, these actuators consist of a pair of active SMA elements where the SMAs are heated and cooled alternately. These actuators are relatively more complex due to the nonlinear nature of the SME. But, antagonistic SMA actuators have the advantage of an additional degree of freedom during activation. As the first SMA is heated, the antagonistic SMA is deformed and activated. Similarly, only upon heating the antagonistic SMA will the actuator be actuated in the opposite direction.

As with most SMA actuators fabricated using SMA wires or coils, the actuation of the actuator results in a linear motion. In application where complex motions are required, the antagonistic SMA actuator is paired with a kinematic stage that converts the linear movement to the required complex motion. Furthermore, they can be implemented into these antagonistic SMA actuators such that they present different behaviours based on the direction of actuation. As mentioned previously, flexure-based kinematic stages have the advantage of increased precision and reduced weight but presents with an inherent stiffness. Thus, this increased rigidity must be taken into account when sizing the SMA active elements.

In the traditional antagonistic SMA actuator, the first SMA, when heated and returns to its original length, deforms the antagonistic SMA. Thus, in this case, the heated SMA must

overcome the rigidity of the cold SMA. The operating points of such a system can be deduced by taking the intersections between the hot and cold SMA curves as shown in chapter [cite](#). In the case of a compliant mechanism, the system is connected to both SMAs at all times. Thus, the inherent stiffness of the compliant mechanism must be taken into account when actuated both SMAs. Therefore, the force-displacement curve of the compliant mechanism, $F(\Delta x)$, can be added to the curve of the antagonistic cold SMA to obtain the apparent load observed by the heated SMA, as shown in [cite](#). The design methodology can thus be adjusted, as shown in [cite](#), such that when the SMA elements are sized and operating points are determined, no unintended behaviours occur. It is important to note that due to the complexity of the compliant mechanism curves, these unintended operating points can emerge causing shorter strokes.

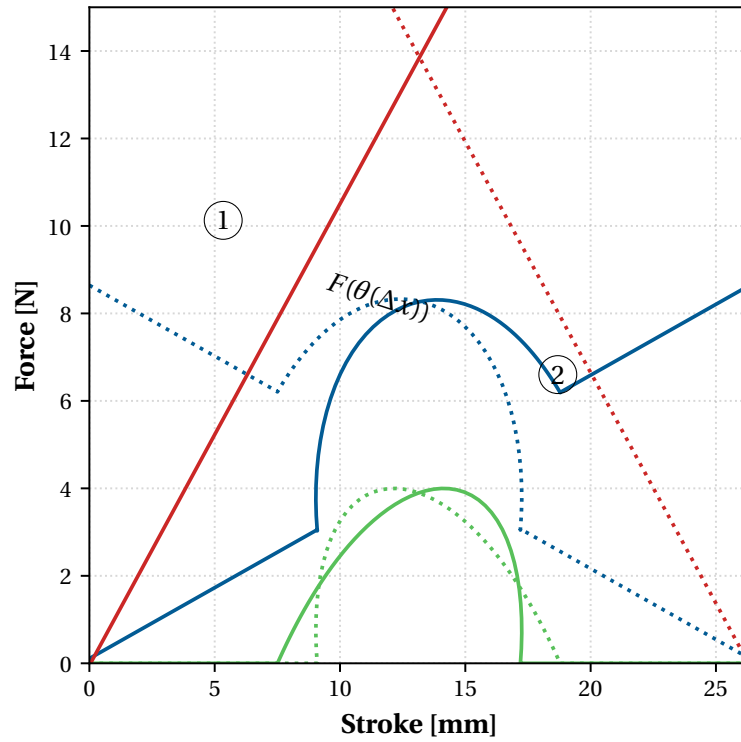

Figure 3.5: The adapted sizing principle of the novel biasing compliant mechanism SMA actuator based on the simplified SMA curves.

Recently, there has been considerable work in developing bistable or multistable actuators. These actuators are able to main a stable position without required any holding energy. This property could be highly beneficial in applications such as grippers. Here, the gripper can stay in the open or closed position without requiring any additional energy. These bistable systems can be created using flexure-based structures, as shown in [cite](#). A axially compressed cantilever beam exhibits bistability and has been implemented in various smart material actuators. In [cite](#), a dielectric elastomer actuator is paired with a buckled beam to create a compact bistable actuator. Furthermore, in [cite](#), a bistable drone-ready gripper is fabricated

and is actuator using an electric motor. This principle can be implemented and actuated using SMAs, as shown in [cite](#). However, the sizing of such a system are missing due to the complex nature of the bistable mechanism and the nonlinear nature of the SMA. Using the proposed, methodology, as shown in [cite](#), the SMA can be sized to present with higher time responses while still able to trigger the bistable positions of the actuator. The accurate sizing of such a bistable SMA actuator is validated later in chapter [cite](#).
